A waveguide photodetector based on semi-insulating indium phosphide (InP) was designed and fabricated. The layer stack for this photodetector was optimized for use as an optical amplifier or laser. By reversely biasing the structure, an efficient, high-speed photodetector was made, which allows for easy integration of source, detector and passive optical components on a single chip. Based on the simulation results, we designed a 30 µm × 1.5 µm waveguide photodetector integrated with a passive access waveguide, which has achieved a 3 dB bandwidth of 35 GHz and 0.25 A/W external responsivity at 1.55 µm wavelength at −4 V bias voltage.

Introduction

The photodetector is a key component in the optical communication system[1]. One of the requirements on photodetectors is a high bandwidth-efficiency product. Compared to the top-illuminated photodetector, the waveguide photodetector has the advantage of almost independent relationship between the bandwidth and the efficiency[2]. Although it has a disadvantage in the fiber-chip coupling efficiency, it is easier to be integrated with laser/preamplifier, AWGs, and other passive components. By optimizing the waveguide geometry and absorption layer thickness of the waveguide photodetector, high bandwidth-efficiency product of 55 GHz has been reported[3]. However, the layer stacks of these reported devices are not suitable for the realisation of semiconductor optical amplifiers (SOA) or lasers, which would limit the flexibility in the monolithic integration of the source and the detector. In[1], the laser is based on quantum wells while the photodetector is based on bulk material, and 12.5 Gbit/s per channel is achieved. To ease the technology for such an active-passive integration, we investigate RF bandwidth of the photodetector by using the same layer stack as SOA/laser. For proper RF performance, we use a semi-insulating InP substrate and coplanar waveguide design. The measurement results show that a 30 µm (80 µm) long photodetector can operate up to 35 GHz (28 GHz) with external responsivity up to 0.25 A/W (0.35 A/W) at a wavelength of 1.55 µm.

Design and Fabrication

The layer stack shown in figure 1 which was previously used for fabricating lasers and optical amplifiers[4], is now being used for the realization of high-speed photodetectors. Due to n.i.d. doping in the film layer, this film layer will be completely depleted even under a small reverse bias voltage. Therefore, in the following calculation, the depletion
layer thickness was taken as 500 nm, the same as the thickness of the film, corresponding to a 44 GHz transit time bandwidth[5, 6]. To achieve the best performance, the waveguide photodetector was designed 1.5 µm wide and deeply etched through the film layer to minimize the capacitance. The calculated series resistances[7] are 105 Ω (40 Ω) respectively for 30 µm (80 µm) long photodetector. By assuming the parasitic capacitance of the bond-pad to be 12 fF[7], the calculated RC bandwidth is about 72 GHz (52 GHz). Therefore, the total bandwidth is about 38 GHz (32 GHz) for 30 µm (80 µm) long photodetector, mainly limited by the transit time bandwidth.

The active-passive epitaxial material was grown on a semi-insulating InP substrate by a three-step low pressure metal-organic-vapor-phase epitaxy (MOVPE)[8]. In the active part, a 120 nm thick absorption/active InGaAsP layer (Q1.55, λgap = 1.55 µm), embedded between two 190 nm quaternary confinement layers (Q1.25), covered by a 200 nm thick p-InP layer. In the passive part, the film layer (Q1.25) thickness is 500 nm, and n-doped (Nd = 6 × 10^{16} cm^{−3}), covered by 200 nm thick n-InP layer with same doping level. The common layers for both active and passive part is 1300 nm gradually p-doped InP and 300 nm highly p-doped contact layer InGaAs. All the waveguides were fabricated by RIE. The access waveguide was shallowly etched to minimize the optical transmission loss, and the photodetector was deeply etched and stopped at 1 × 10^{18} cm^{−3} n-InP layer below the film. The etching depth of the photodetector is about 3 µm. Polyimide was spun for passivation and planarization. Before metallisation, firstly we etched back the polyimide in the barrel etcher to expose p-InGaAs. Afterwards, we used the photoresist as a mask to protect the exposed p-contact, and etching the polyimide directionally to open n-InP contact layer. To form the metal contact, Ti/Pt/Au were evaporated on the top p-InGaAs and the lateral grounds (n-InP) through lift-off. Due to the limitation in the lift-off, the gap distance between the p- and n-contact was designed 10 µm. To minimize the RF transmission loss, the fabrication proceeded with the electroplating until the thickness of the gold is about 1.5 µm, which is three times larger than the skin depth[4]. The crosssection and the top view of the finished device are shown in figure 2. The photograph shows the photodetector with its coplanar waveguide transmission line, which are tapered.
Experimental results

The optical signal is coupled into the waveguide via the cleaved facet of the chip. All measurements were performed using on-wafer probing technique. The photodetectors exhibit low dark current, less than 50 nA dark currents at $-4$ V bias voltage for the photodetectors up to 80 $\mu$m long, figure 3.

On-wafer S-parameter measurements are performed in the range of 10 MHz to 67 GHz with a lightwave component analyzer and a 50 GHz RF-probe. The photodetector was biased at $-4$ V through a 67 GHz bias tee, and the injected wavelength from the lightwave analyzer is 1.55 $\mu$m with $-1$ dBm optical power. The measured small signal frequency response is given in figure 4. The 30 $\mu$m long photodetector achieved 35 GHz 3-dB bandwidth, while the 80 $\mu$m long photodetector obtained 28 GHz bandwidth. The measured external responsivity in the left axis showed that the external responsivity is 0.25 A/W and 0.35 A/W for 30 $\mu$m and 80 $\mu$m long photodetector, respectively. The measured RC bandwidth from $S_{22}$ is in agreement with the calculated RC bandwidth. The measured total bandwidths are slightly smaller than the calculated bandwidth mainly because the depletion layer thickness is actually thicker than 500 nm under $-4$ V reverse bias voltage, which further decreased the transit time bandwidth. Furthermore, the actual series resistance extracted from $S_{22}$ is about 125 $\Omega$ (60 $\Omega$) for 30 $\mu$m (80 $\mu$m) long photodetector, higher than the calculated value, which is due to the fabrication and the series resistance of the transmission line and the bondpad.
Conclusions

We demonstrated high-frequency waveguide photodetectors in an amplifier layer stack operating up to 35 GHz with 0.25 A/W external responsivity. This result enables the monolithic integration of source and high performance photodetector based on flexible butt-joint active-passive material without the need for a dedicated detector layer stack. This work is partly funded by the Dutch National Broadband Photonics Access project and the Dutch National Smartmix project Memphis.
